Abstract: Solar photovoltaic (PV) energy technology can play a key role in decreasing the amount of carbon emissions associated with electrical energy production, while also providing an economically justifiable alternative to fossil fuel production. Solar energy technology is also extremely flexible in terms of the size and siting of technological development. Large scale PV farms, however, require access to large tracts of land, which can create community-scale conflict over siting solar energy development projects. While previous scholarship offers frameworks for understanding the mechanisms at play in socio-technological system transitions, including the renewable energy transition, those frameworks fail to center community priorities, values, and concerns, and therefore often do not provide an effective means of addressing community conflict over solar siting. This paper provides a conceptual exploration of how a proposed framework can guide decision making for solar development across multiple scales and settings, while also illuminating the potential barriers and bottlenecks that may limit the potential of solar energy development to occur in scales and forms that receive community acceptance and at the pace necessary to address the greenhouse gas emissions currently contributing to the rapidly changing global climate.

Keywords: energy decision making; energy transitions; photovoltaics; solar energy; sustainability; community; energy democracy; energy security; energy sovereignty

1. Introduction

Solar photovoltaic (PV) energy has undergone an incredibly rapid industrial learning curve [1–3], resulting in continuous cost declines [4,5]. The International Renewable Energy Agency (IRENA) confidently predicts that PV prices will fall by another 60% in the next decade [6]. Even without expected future cost reductions, any scale of PV, from residential to industrial, provides a leveled cost of electricity (LCOE) [7] lower than the net-metered cost of grid electricity [8–10]. PV economics ensure that coal-fired electricity is no longer economically competitive, and solar is now normally the least costly electricity source [11,12]. In addition, there are several technical improvements like black silicon [13,14] and bifacial PV [15,16] that are poised to gain market control and further drive down costs [17]. Unsurprisingly, solar PV is the fastest growing electricity source, with capacity reaching about 505 GW, or 2% of global electricity production, in 2018 [18], and reaching at least 627 GW by 2019 [19]. The rapid improvements in PV and energy storage technologies are arguably outpacing social recognition of the urgency with which energy systems need to transition to avoid the worst of the catastrophic impacts associated with the continued use of fossil fuels for energy production and the policy tools being used to propel this transition. For example, despite the fact that the LCOE of community and

utility-scale solar is competitive with coal and natural gas, a combined 65% of Americans think that climate policies would have no impact or would hurt the economy, and while an overwhelming majority of Americans would like to see more reliance on solar and wind energy, 29% believe that climate policies will make no difference for the environment, and 15% believe that climate policies will do the environment more harm than good [20]. This paper centers on these social considerations and presents a framework that can incorporate social values in ways that may improve the speed and the outcomes of this transition.

PV has other advantages besides costs. Renewable energy technologies like solar PV may create emissions during manufacturing and installation but produce emission-free electrical energy once installed and, overall, have an excellent ecological balance sheet [21]. The generation and delivery of electric power using conventional thermal fossil-fuel driven power plants consumes almost two-thirds of the primary energy delivered to the grid [22,23]. Globally, nearly a billion metric tons of carbon dioxide equivalents can be attributed to “compensatory emissions” related to a lack of efficiency in generation and transmission. Forty to fifty percent of those emissions can be cut by improving grid efficiencies [24], which could be achieved with distributed energy resources. PV is inherently distributed and modular so it can be located near or even on the structure of the electricity consumer to provide for energy needs even as loads shift over time. This distributed generation (DG) with PV has several technical advantages: (i) improved reliability [25,26], (ii) enhanced voltage profiles and power quality [27], (iii) reduced transmission and distribution losses [28], and the concomitant transmission and distribution infrastructures deferrals. In addition, PV has been long established as a sustainable energy source [29], with well-documented superior environmental performance to conventional sources of electricity, as directly generating electricity from solar energy is free from fossil energy consumption and greenhouse gas (GHG) emissions during its operation. When compared to the advantages of solar energy, fossil fuel-based energy generation no longer makes technical or economic sense.

Despite these advantages, PV continues to face challenges that limit or slow its development. Solar is an intermittent resource (e.g., it only works when the sun is shining). Solar energy is diffuse, so PV equipment requires large surface areas. According to the Energy Information Administration, the average American household uses 877 kWh of electricity per month [30]. In general, the average non-shaded residential home has more than enough roof area to meet its energy needs; other structures, such as large retail stores, would need to start covering the parking lots with awnings to meet energy needs with distributed PV [31]. Densely populated cities do not have enough surface area available for PV to meet their electricity needs (let alone transport and heating needs covered by vehicle electrification and heat pumps, respectively). Large areas of open land are needed for PV [32], and they are generally located in rural areas.

Due to these needs, land use conflicts are a growing problem for large-scale PV. These siting conflicts were once relegated to wind farm development [33–36], but now shape public opinion regarding solar energy projects [37,38]. Using solar may be technically more efficient, as well as having a lower LCOE than conventional power plants [7], but conflict over siting—questions about where to locate what size PV systems to support whose energy needs—remains an issue.

Across the United States, individual states as well as local units of government have set goals to reduce or eliminate carbon emissions, either via legislation or executive action [39]. The utility sector is responding accordingly. In November 2020, six Midwest utility holding companies said they expect to retire a combined total of 5.8 GW of coal-fired capacity by the years 2022–2023 and, over the next several years, buy or install 4 GW of solar generation, 3.6 GW of wind generation, and just over 1 GW of electric battery storage [40]. Rarely included in such breathless announcements is the fact that developers and utilities have often yet to secure the requisite number of acres to host the utility-scale PV developments upon which their projections rely.

Options like rooftop solar and community-scale solar developments, which tend to distribute the economic benefits of renewable generation more equitably than utility-scale developments, are popular with host communities, as are efforts to site larger developments on brownfields and other post-industrial sites [41]. There is little doubt, however, that achieving complete independence from fossil fuels in electricity production, transportation, and heating, will require large-scale development, even if the amount of land necessary and which types of land to be utilized is disputed (i.e., agricultural land, ecologically sensitive land, and previously forested land are contested). Given these variables, the question of how to achieve a renewable energy transition in an equitable and cost-effective way has been the purview of monopoly utilities, state public utility commissions, lawmakers, and federal regulators across much of the United States. This top-down regime, a product of the historical need for large, up-front capital investment in energy production and distribution, has rarely given serious credence to the priorities of the communities it serves [42]. The need, however, to site utility-scale generation, as well as the rapid innovation and accessibility of distributed generation technologies, is altering consumers' relationships with their energy providers. In a sense, the renewable energy transition has forced utilities back to the negotiating table, as communities and individual consumers reexamine a century-old unwritten compact about the rights and responsibilities of each.

In this new dynamic, the framework explained and applied below could help improve decision making that increases the deployment velocity of PV by attempting something radical: centering energy policy in the nexus of the cultural, ecological, and economic priorities of the communities that produce and consume it. This could help provide direction for community decision-makers and, by revealing the complexity and web of interconnected factors that matter, could lead to solutions that ensure greater cultural and economic resilience. This proposed framework is explored conceptually below through application to the questions and decision-making factors that may shape the priorities and choices a community makes regarding solar energy development.

2. Socio-Technological Systems Transitions Frameworks

Arguably, the most well-developed framework for examining socio-technological system transitions is the multi-level perspective [43–46], also known as the MLP. The MLP conceptualizes transitions in terms of interactions across actors and institutions and argues that “sociotechnical transitions come about through interacting processes within and between the incumbent regime, radical niche-innovations, and the sociotechnical landscape” [43] (p. 225). MLP is a dominating framework for exploring the various mechanisms and pathways involved in successful transitions to renewable energy adoption in communities [47] and across the “sociotechnical landscape.”

The MLP is in some ways a critique and response to Christensen's early innovations framework, which focused on disruption from niche innovations challenging incumbent rule [48]. Christensen's framework focused on disruptive technology, while MLP “broadens the unit of analysis from technological products to sociotechnical systems that provide societal functions” and that “consist of an interdependent and co-evolving mix of technologies, supply chains, infrastructures, markets, regulations, user practices, and cultural meanings” [43] (p. 225). The MLP aims to broaden the factors considered as analytically relevant to understand transitions to include “consumption, cultural, and socio-political dimensions” [43] (p. 227).

Previous scholarship based on the MLP framework includes work examining the role of power and politics [45]. Based on employing a political economy perspective, the MLP can be utilized in a way that is attentive to how incumbent regime actors (those who benefit financially from continued reliance on fossil fuels for electrical energy) can shape discourse, policy, and possibilities in the energy transition through multiple forms of power, including instrumental, discursive, material, and institutional. The MLP also allows for considerations of resistance to incumbent regimes from both niche-innovations and the broader socio-technological landscape. Analyzing the power and interests of the

“regime” construct reveals a failure to account for “problems of agency and the politics of transitions” [49] (pp. 143–144), as the potential involvement and influence of collective groups of actors has not been researched adequately, according to some scholars, which is critical in understanding the nuances of socio-technological energy transitions, particularly in previously colonized country contexts [49].

By starting with an emphasis on “socio-technical systems,” however, the MLP is inherently focused on material systems and the institutional systems that govern them. There is less room in MLP for considering the role of cultural values, priorities, and identities in informing and directing transitions in grounded, socially embedded contexts. Arguably, the MLP framework allows inadequate space for conceptualizing how real people and their real lived priorities can inform decision making in energy transitions (and other socio-technological system transitions). The framework presented here attempts to address these critical deficiencies, as they are applicable across the spectrum of development stages, with particular focus on accounting for agency through the prioritization of community values and the subjugation of technical, economic, or political feasibility to community priorities.

The framework described below is inspired by the medicine wheel or sacred hoop, representing the philosophy adopted by many Indigenous Nations of being in balance through life’s natural and cyclical transitions. As a whole, the framework is intended to conceptually represent knowledge and relations while maintaining balance through continuous transitions of all kinds. These teachings offer a guide for finding a respectful and ethical path through a socio-technological system change.

The relationships among the interconnections in Figure 1 start with four foundational questions (as described below) [50]. These four foundational questions guide the application of this framework. This framework also suggests particular research questions (RQ) that can guide empirical research employing this framework (as also explored below):

RQ 1.1: What community visions, values, perceptions, and priorities are associated with which risks, barriers, and opportunities for renewable energy system transitions?

RQ 1.2: How does this vary across the community context?

RQ 1.3: What trade-offs or compromises do communities make when making energy decisions?

RQ 2.0: What socio-cultural, technical, biophysical, and regulatory variables facilitate or impede renewable energy transitions given the benefits, risks, and opportunities associated with renewable energy development?

RQ 3.0: What novel technologies and approaches can facilitate energy transitions and how can decision-support tools enable communities to envision alternative futures and make energy transition decisions while considering relevant social, technical, and biophysical impacts?

RQ 4.1: How does community participation in energy decisions shape energy transitions and community well-being?

RQ 4.2: What policies and management options, across which community and state scales, best empower community decision making and are most likely to facilitate renewable energy transitions?

RQ 4.3: How can we support communities in making choices that involve difficult tradeoffs between their own values and visions, and those of other communities, regions, and scales?

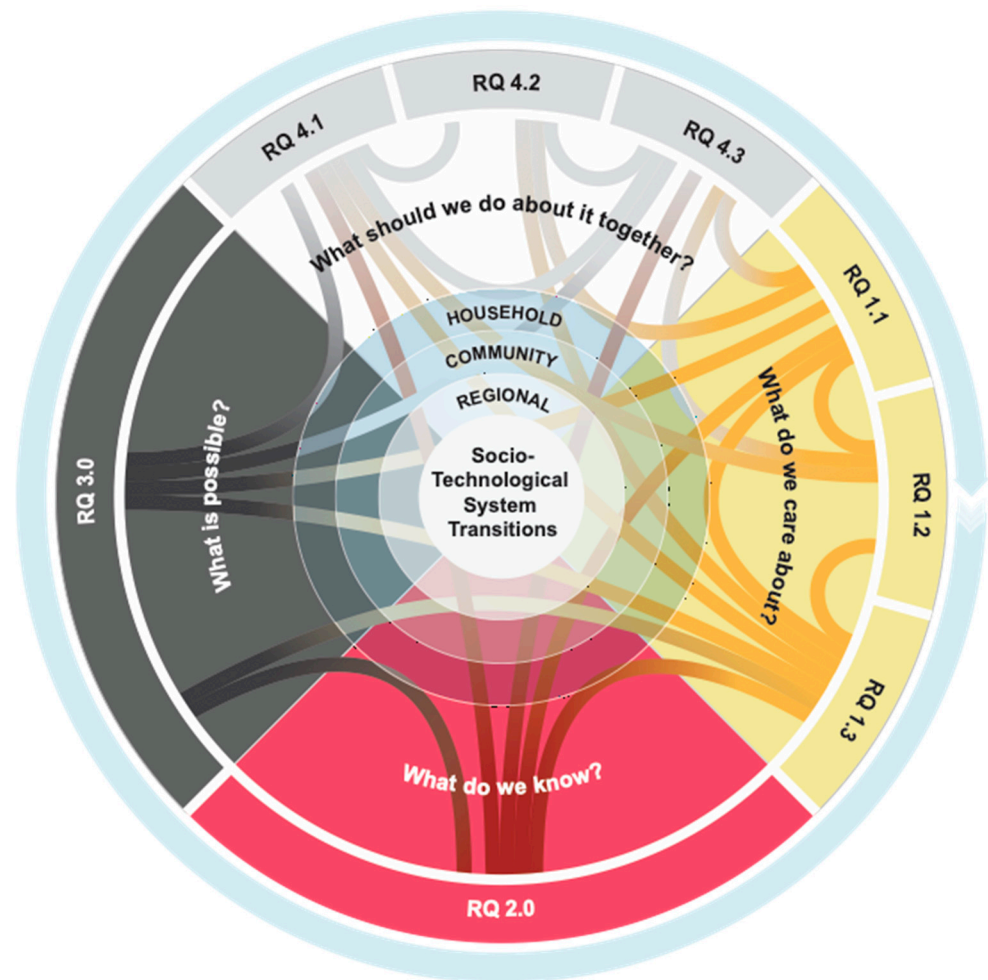

Figure 1. Socio-technological Systems Transitions Framework.

3. Applying the Framework

Applying this framework begins in the East (like the sunrise), with the question “What do we care about?”. The framework is based on the proposition that, instead of starting by asking what is technically, economically, or politically possible, we instead start by asking about community cares, concerns, priorities, and values. The novelty of this approach is that it requires that technologies be situated within and that technological transitions be emergent from community priorities rather than starting with technical or economic considerations and then asking if they align with or contradict what a community actually cares about. A community’s priorities may be situated, at least in part, within their existing socio-technological contexts. The novelty and value of beginning with a community-centered, rather than technologically or economically centered framework, involves understanding the ways in which current systems align with community values and the inability of existing systems to identify community challenges, future goals, and priorities.

3.1. What Do We Care about?

Renewable energy transitions are often framed in terms of the urgent need to address climate change and their immediate climate benefit. A plurality of individuals accept the fact of anthropogenic climate change, and with it, a shared responsibility to achieve carbon neutrality as quickly as possible. In this sense, the “We” in question is none other than humankind, and indeed, all life on earth. If the primary concern is GHG emissions, then a rapid transition using PV can meet the goal, even when considering life cycle carbon emissions [51]. PV development has increased efficiency for decades [52,53] across

a wide range of PV materials, and each small increase in efficiency, using the same physical processes of production, not only reduced costs that increased the wide adoption of PV [54], but also the GHG emissions reduction potential of the technology has increased. In a conventional utility model, this would be done with utility-scale solar development and would technically meet that goal in the most economically efficient manner in a way that smaller systems could not [55]. Yet communities often care about the impacts of their electrical energy systems for reasons beyond GHG emissions. If they accept any responsibility at all, community actors may weigh a broad mandate to reduce emissions against specific ecological and economic concerns.

For communities who do share collective care for the environment or natural world, GHG emissions may be just one component of concern. Ecosystem integrity, habitat preservation, or species protection may also be community cares, and large, utility-scale solar systems may not align with these community priorities. In California, where there is a mandate to achieve zero-emission electricity production by 2045, there have been protracted battles surrounding proposed utility-scale solar developments in the California Desert [56]. Though the state now requires rooftop solar to be a feature of all new construction [56], renewable industry advocates still anticipate that the state will fall far short of its goals unless it aggressively constructs utility-scale solar farms. Roughly 4000 MW of solar sited on 30,000 acres has been proposed or is under construction. State modeling shows that California will need 90,000 to 125,000 more MW over the next 25 years [56]. Project permits have been contested by a coalition of tribal and environmental groups who argue that the development amounts to “a gigantic assault of these industrial projects on desert habitats and cultural sites”, even though they favor California’s carbon-neutral policy [56].

Similarly, Maryland has had difficulty siting utility-scale solar developments, despite a statewide goal of producing half its energy from carbon-neutral sources by 2030, with 14.5% of that coming from solar energy. A “responsible siting” task force convened by Gov. Larry Hogan concluded that up to 2.9% of prime farmland could be lost to solar development, even though the state has made strong efforts to preserve such land in the past [57].

As we see in these instances and many others, there is frequently an imbalance between the perceived economic and ecological burdens communities are asked to absorb for the sake of hosting utility-scale solar and that of the communities who would broadly benefit from lower utility costs and reduced carbon emissions. This can be true whether or not the energy produced by a project will be owned or purchased by a city or township’s incumbent electricity provider. Utility-scale is cost-efficient precisely because it is concentrated, enabling one project to serve many households and businesses over a broad geographic area. Utility-scale solar benefits from scale in purchasing power for components, permitting, and even in labor, using all of the same equipment, but these benefits do not necessarily accrue to the host community.

In many cases, developers can design mid- to large-scale solar projects that maintain ecosystem functions, habitat access, and agricultural productivity [58,59]. A growing “agrivoltaic” movement to profitably co-site solar projects with livestock grazing and crop production has seen early promise [60]. Conventional PV farms can be intercropped with some agricultural products with no changes, and for other crops, developers can install solar panels with mounts tall enough for equipment and animals to pass under while justifying the increased expense with increased economic productivity of their land. Likewise, solar farms can host pollinator-friendly habitats that benefit agriculture and wildlife in the local areas.

Another approach to the application of solar that reduces conflict is floatovoltaics (FPV) [61–63], which is the deployment of floating PV onto water surfaces. Similar to agrivoltaics, FPV has a synergistic effect where the water cools the PV, thus reducing their operating temperature and improving the PV electrical conversion efficiency [64]. At the same time, the PV can reduce evaporation rates and thus improve water conservation [65]. FPV can be both on-grid and off-grid [66], as well as the base of microgrids [67], as in India.

FPV can be deployed on a small scale in temporary summer-home systems [68], but also on a utility-scale in multi-MW permanent farms [69], as in the Seychelles. In perhaps the most efficient use of surface area, FPV and agrivoltaics can be combined to make aquavoltaics, where FPV are used in aquaculture. [70] Although there is enormous potential for FPV, even when artificially restricting deployment to human-made waterways [71], there are still obstacles to overcome, most of which are knowledge-based [72] (see Section 3.2 below).

As this framework demonstrates, starting with the question of what communities care about can reveal new areas for inquiry regarding the knowledge needed to meet a community's energy needs with available technology. In space-constrained environments or areas that culturally identify with agricultural land or waterways, these innovative technological applications may be particularly appropriate. Even with either agrivoltaics or FPV, in sensitive ecosystems or in areas with threatened species, the habitat impacts of solar may be undesirable in terms of alignment with community concerns. In this case, solar energy development through distributed generation may be desirable (i.e., rooftop installations and small ground mount systems). While these options may represent a more complicated process than utility-scale development, the alternative path honors varying and different community priorities. Given the nature of utility ratemaking, the costs of these projects will eventually be passed to ratepayers, some of whom may presumably object to funding anything beyond the most cost-efficient, large-scale development. Although, it should be pointed out that in many scenarios, because customer-owned PV often produces electricity costing less than the retail rates by enabling customers to invest in the systems, costs can be avoided for the utilities during a transition. Questions arise regarding who is included or excluded in the definitions of community and how differences across communities who share in the decision making and the consequences of energy system transitions are addressed. These considerations are further explored in the discussion below.

The primary cares regarding energy systems may include community control (including management, ownership, and sovereignty), economic concerns in which communities seek to prioritize energy transitions that reduce the cost of electricity access, or care for the environment. In communities that relate the direct application of energy to its end use, such as solar-heated water or electrically pumped groundwater used for bathing, cleaning, and agriculture, there is heightened "awareness of environmental rhythms" [73] (p. 9), creating increased efficiency and ingenuity, resulting in a more sustainable use of resources. In a report to the U.S. Department of Energy (DOE) published in 2008, the Saginaw Chippewa Tribe of southeastern Michigan presented "a vision to become self-sufficient in its energy needs and, in respect and concern for the next seven generations, to maintain its culture and protect Mother Earth", stating "sustainable green energy sources, such as solar, wind, and biomass energy, are the best energy paths to travel" [74] (p. 3). These communities reject what they view as the profit interests of privatized, corporate, fossil-fuel-dominant business models in favor of democratically-managed, publicly-owned RE systems that dismantle concentrated economic and political power. These systems serve the public good by reducing GHG emissions, creating local jobs, and providing equitable access to energy [75]. In these cases, technical or economic considerations become less salient than issues of ownership, decision making, resilience, and sovereignty [76]. Community energy sovereignty can be achieved through the integration of socioeconomic, political, and technological dimensions that link social justice and equity with energy innovation to democratize energy in support of autonomy, security, and resiliency [76]. Since 2008, the Saginaw Chippewa Tribe has developed physical energy infrastructure, including electrical substations, wind and solar generation, and power purchase agreements. On 30 October 2019, they established the Saginaw Chippewa Electric Authority to manage, operate, and maintain the electric distribution and generation system for their community [77].

For many communities, their primary concerns may not be directly related to energy at all. In low-income country contexts, consumers demonstrate more concern about the impact of their consumption than consumers in high-income country contexts, and are more likely to associate consumption habits with the degradation of personal and environmental

health and take action to mitigate the effects [78]. In some low-income country contexts, a lack of adequate electricity energy provision through centralized distribution can motivate desires to learn more about solar energy as a decentralized and locally controlled option, particularly in the context of private sector actors who are motivated by financial considerations [79]. This transition framework suggests that learning about what communities care about—whether that be unsustainable consumption, equalizing access to economic wellbeing, decreasing the economic burdens of poverty or precarity in the community, increasing economic development opportunities, increasing jobs in the local community, protecting local or global environments, promoting community-level independence and resilience, increasing community amenities, reducing health impacts of fossil-fuel-driven air pollution, or any other community consideration—is the first and most important step in developing energy transition planning and decision making, which can succeed by aligning with community priorities.

3.2. What Do We Know?

When it comes to solar PV energy technology, there are several known and well-documented technical, economic, and social advantages:

- PV are massive net energy producers: For some time now, PV modules have been shown to produce far more energy than is used to produce them [80]. PV efficiencies have steadily climbed [81], only driving the energy return over energy invested higher (with some PV “paying” their energy back in a year) [82].
- PV has “generational” long lifetimes and warranties: PV modules, in general, carry a warranty for 90% production at 10 years and 80% production at 25 years [83]. That means 25 years after the purchase of a solar panel, consumers can expect it to still be outputting 80% of its rated capacity. Many studies have shown that PV degradation rates are below 1%/year [84–89].
- PV has high reliability and durability in all environments where humans live: PV is reliable under the most extreme environmental conditions, from small losses due to snow in harsh Canadian winters [90] to scorching desert climates in Egypt [91].
- PV has low maintenance costs and no fuel costs: Solar PV systems do not require frequent inspection or maintenance [7] and require no fuels to operate (and thus no transport and storage of fuel either). This is a distinct benefit for communities globally without access to professional operations and maintenance (O&M).
- PV reduces sound pollution: PV systems operate silently and with no movement (most systems) and minimal movement (single and dual-axis trackers).
- PV is extremely safe: PV systems do not require the use, transport, or storage of combustible fuels; they have no environmental emissions during use and are electrically safe when properly designed and installed. They also produce no nuclear waste.
- PV allows for flexible system architectures with grid-tied, decentralized generation, and grid independence: PV systems may operate independently of grid systems, but also can improve grid reliability with decentralized generation [92,93]. PV systems can be operated off-grid [94] and, when coupled with storage technologies and/or hybrid generation, can provide lower-cost power for those with poor electric infrastructure [95], as well as those in rural and low-income, previously colonized communities continuing to lack basic infrastructure.
- PV performance improves in cold and high altitudes: PV generation increases as the temperature drops [96,97], as well as at higher elevations (because of increased solar flux).
- PV systems are flexible and modular: Unlike conventional systems, PV modules may be added to photovoltaic systems to increase available power; they can be deployed almost anywhere the sun shines at scales appropriate for the situation. This is simply not possible with most conventional electric sources.
- PV can create jobs and enhance tax revenues: Currently, more than 250,000 Americans work in the solar industry [98,99]. Globally, the solar industry employs more than

3.6 million people [100]. Depending on the tax regime, some governments that support solar see a return on investment (ROI) based on taxes; the Canadian government, for example, would earn a profit under any scenario supporting PV, including giving multi-million-dollar PV plants away for free [7].

- PV reduces the liability costs for conventional power plant operators: For the nuclear case, reduced potential liability from nuclear disasters [101–103] is so substantial that just displacing the nuclear insurance subsidy to solar would provide an additional 48,600 TWh of electricity over nuclear worth \$5.3 trillion [104]. In fossil fuel cases, moving to solar would reduce carbon emission liability costs, which, similarly, could be worth hundreds of trillions of dollars [105].
- PV can enable low-income countries to leapfrog conventional centralized power plants and their concomitant problems: By encouraging the adoption of PV, rural areas in low-income and previously colonized country contexts, who have not built economies based on extractive exploitation of global economies, have particular promise to leapfrog conventional power sources, and the pollution and economic challenges they represent [106–108].
- The full values of solar (VOS) have shown numerous economic benefits [109–114]:
 - Reduces conventional electricity market prices due to reduced peak demand
 - Provides a valuable price hedge from using a free, renewable fuel rather than variably-priced fossil fuels
 - Reduces costs due to avoiding new transmission and distribution infrastructure to manage electricity delivery from centralized power plants;
 - Reduces need to build, operate, maintain, and buy fuel for fossil fuel-generating plants
 - Reduces reserve capacity costs, distribution, and transmission costs
 - Reduces electric outages due to a more reliable, distributed electric power system
 - Reduces future costs of mitigating the environmental impacts of fossil fuel and nuclear generation
 - Avoids health liability costs as well as saves lives (e.g., replacing all of coal-fired electricity with solar energy would save ~52,000 American lives per year [115]).

The points above represent collective knowledge about solar. The distribution of these technical, economic, and social benefits, however, continue to be unknown, at least partially, because the distribution of benefits is shaped by diverse policy and regulatory regimes and a multitude of siting, investment, finance, and ownership choices that are made at the state, municipality, utility, and community levels. While the benefits may be undisputed, the matter of who receives these benefits, based on what specific kinds of choices shape development, is still an open question, representing factors unknown for communities to explore—and research illustrates that the distribution of these benefits is a primary concern shaping public support for solar energy development [116,117].

Despite the numerous benefits, solar PV also has inevitable, as well as potentially negative impacts. There are real negative environmental consequences of PV production and disposal [118]. These negative impacts could be partially offset by recycling [94], and policies should encourage responsible industrial practices [119]. Solar PV is a capital asset and often consumers do not have access to capital, which reduces PV velocity and demands some form of financing [120–123] or securitization [124]. Life cycle assessments (LCA) performed on five common PV systems demonstrated that, while manufacturing and installation processes consume energy and generate some GHGs, the energy payback time (EPBT) for PV falls within the range of 0.7–3.5 years, with GHG emission rates an order of magnitude smaller than those of fossil-based electricity [125].

Because solar is an intermittent resource, it must be coupled with other renewable energy sources like hydro or wind, as well as storage, to completely offset all conventional generation. Intermittency can be reduced and accommodated by interconnecting intermittent resources, forecasting their variation, and integrating them with dispatchable renewable sources (such as hydropower, geothermal, and biomass). Demand response

(or demand-side management), can shift flexible loads in order to optimize intermittent production. With the growth in demand, electrical energy storage (EES) and power balancing technologies are rapidly developing, with year-on-year growth of EES in emerging markets expected to reach 40% through 2025 [126]. Various means of EES can be utilized for frequency regulation, flexible ramping, black start services, and to reduce curtailment of variable renewable energy production [127,128].

Regulations are evolving as well, for example, the U.S. Federal Energy Regulatory Commission (FERC) FERC Order No. 2222, approved in 2020, creates pathways for storage and distributed energy resources (DERs) to participate in wholesale markets serviced by regional transmission operators or independent system operators (RTOs/ISOs) by establishing distributed energy resources (DERs) as a market participant category and allowing them to aggregate in order to satisfy minimum size and performance requirements [129]. It is necessary to develop both these technologies and the enabling regulations that support their deployment at a pace adequate to fully leverage solar energy's potential contribution to collective electrical energy needs.

The points above address what is known technically and economically about solar energy technology. There is, however, another way to address the question posed above about what is collectively known. Individuals and communities know things through their lived experience, through their traditions and cultures, and through intergenerational ontologies, knowledge systems passed down through generations representing collective understandings of reality.

Some communities, including within the United States, hold different understandings of technologies and the willingness to accept their potential impacts. For example, consider the viewpoint of a community regarding the impact of a PV system on a particular wild animal whose habitat may need to be drained to install a solar farm. For Indigenous Nations communities in the United States and throughout the world, the collectively held understanding of reality may involve extended understandings of kinship, relationality, and responsibility [130]. As just one example, there are multiple possible perspectives for understanding the nature of the beaver—is this animal a pest who creates damage to waterways, or is it a relative, demonstrating to the world the building capacity of making homes in ways that are synergistically beneficial for other species and entire ecologies? The answer depends on ontology [131], which can vary across communities as well as across time and place. There are different ways to answer the question about what is known regarding how humans live and relate to the rest of the world, and the answer to these questions will shape how communities make decisions regarding energy development. In this example, understanding animals as relatives changes whether or not it is acceptable to relocate individual animals or damage the habitat of species to pursue rapid utility-scale solar development. Similarly, whether a community knows that their utility company is trustworthy, their trees are sacred, or myriad other knowledge objects or systems, will shape priorities and possibilities for community-supported solar development.

3.3. *What Is Possible?*

Answering the question “What is possible?” depends on the answers to the questions above, but also depends on the utility, regulatory, and policy context, as well as the economic and technical context of any given community. What is possible depends on a community's willingness to invest, environmental factors such as land availability or shading, the quality of local infrastructure, roof engineering, access to capital and financing, local regulations, state and federal regulations and incentives, and a multitude of other economic, technical, and regulatory factors. Some of these conditions of possibility may be in the community's power to change, while others may not. A community might choose to look at available options given current incentives and regulatory regimes. On the other hand, they may decide to advocate for changes to the regulatory regimes in which they are situated, in a way that better aligns with their goals and values.

One way to address this question focuses on what is possible in the current regulatory regime. Given the need for power purchase agreements (PPAs) to ensure that generated solar energy can be integrated into the grid and compensated at a fair market price, utility structures must have existing options for PPAs for community investment in solar energy to make sense. In the United States, some IOUs create barriers to integrating solar into the grid [132], even if there is a community willing to host and a willing financial investor. For large scale solar, what is possible may also depend on policy beyond energy policy, as land access, zoning issues, and policy regarding the use and taxation of agricultural land can all shape whether or not solar development is possible.

Where they have siting jurisdiction, counties and townships have an opportunity to proactively plan if and how they would allow utility-scale renewable development into their communities [133]. Local governments can use the planning and zoning process to create height restrictions, setbacks, and land use requirements that either signal to developers they are cleared for approach, or that utility-scale projects are unwelcome. Agricultural policy is often restrictive and limiting for solar development. As described above, there is a concern about PV farms offsetting food production when sited in agricultural communities [134]. This can be partially ameliorated by careful planning and through agrivoltaics (the co-location of PV and conventional crops) [135,136]. When they are open to development, municipalities may include ordinance language, encouraging or requiring pollinator-friendly habitats and other agrivoltaic features [133]. Municipalities that own their own electric utilities and would like to build medium- or large-scale renewable energy projects can include such parameters in development.

The operation of the current U.S. federal economic incentive as a tax credit also limits the possibilities for entities without a tax appetite, as one must have significant tax liabilities in order to take advantage of these credits [137]. Municipalities and other non-profit entities cannot benefit financially from a tax incentive for solar investment. In the U.S., municipalities are limited in the extent to which they are allowed to accrue debt, hindering their ability to make public investments in solar energy development. Limited public investment in solar encourages development by private corporate actors, who may try to co-opt new innovation in order to stymy market disruptions those innovations may create, and reinject capital into incumbent systems. This may slow the pace of clean energy transitions, and also acts to suppress technological innovation, and undermine opportunities for democratic control of energy resources [138]. Municipal, community, and cooperatively owned and controlled energy producers have the agility to prioritize energy security, energy democracy, and community development, as they are not beholden to generate profits for shareholders [139] but are instead accountable to citizens and their members, respectively.

Addressing the conditions of possibility may also require collective organization to change the incumbent electrical energy regimes. These regimes have resisted transitions to renewable energy, citing economic and technical difficulties. However, it is perceived that the more plausible motivation is the preservation of profits from existing business models, regulatory frameworks, and subsidies. Incumbent regimes have formed coalitions with politicians and think tanks to undermine climate science and resist renewable energy transitions [140], including reforms in utility structure, as well as policy and regulatory structures that shape solar energy technology development. Some of the ways a community may influence the existing regime require investments, including economic investments in publicly-owned solar. Due to the political and market power of incumbent regimes, existing business models, and regulatory frameworks, this investment requires government intervention [141]. In the U.S., this could take place through initiatives that would be supported by the passing of House Resolution 109, 2019–20, also known as the Green New Deal [142]. Communities must also invest time and knowledge to advocate for policy change. Some of the policies that can be changed to improve the conditions of possibility for solar energy development include subsidy reforms [143], eliminating solar rooftop bans in homeowner's associations, caps on carbon production, eliminating regulatory obstacles

to grid integration of solar and related technology, eliminating caps on grid-integrated solar [132], improving the transparency and financial benefits associated with net metering and feed-in tariff programs [144], improving and utilizing energy efficiency programs to lessen energy demand and the associated economic and environmental impacts, and advocating or organizing for an increase in public utility ownership [145].

3.4. What Should We Do about It Together?

In short, the answer to this question depends on the answers to the questions that precede it. This, we argue, is the value of this framework. Instead of starting with an externally identified objective (such as increasing renewable energy or solar energy deployment), this framework begins by centering and empirically examining community concerns, values, and priorities. It also requires addressing empirically the conditions and state of knowledge, both knowledge of technologies and the knowledge collectively held and known to be true by communities [146]. Both community concerns and community knowledge will shape the conditions of possibility for energy transitions; asking about these conditions of possibility also reveals the myriad economic, technical, structural, and regulatory factors that determine what is possible for communities. Researchers can best support energy democracy and energy sovereignty in community scale energy transitions by using these questions to inform proposals for what should be collectively done to support energy transitions that align with community preferences.

4. Discussion

The application of this framework reveals several conceptual and empirical tensions. The first is the very nature and definition of community in community energy transitions research. Communities are never perfectly homogenous, and capturing the diversity of community perspectives, including tensions or divergence within a community, is also key to understanding a community's perspective; this framework is focused on finding generally shared understandings, but application should not ignore differences or contradictions, as they can also help inform community decision making. Also, how a community is defined may depend on already existing dynamics of inclusion and exclusion that researchers should not ignore; intentionally attending to such dynamics is key for valid empirical research.

Furthermore, the nature of community in energy research is inevitably complex, as energy systems may be developed in communities that do not benefit financially or otherwise from that development. While utility territories (the geographical space where a utility is given a monopoly to operate) represent a simplified way to define community, utilities may invest in renewable energy systems sited outside their territory, and communities may self-identify in ways that are not at all based on utility providers. Attending to this complexity is an essential component of applying the framework proposed above.

5. Conclusions

This paper explored how a proposed framework for understanding socio-technological system transitions can be applied to solar photovoltaic energy technology development to reveal the complex web of factors involved in solar energy decision making. By starting with what a community cares about, choices regarding the scale, siting, and ownership of solar energy development can be informed by community priorities. By asking what is collectively known, both about a technology and by a community, the framework can be used to reveal gaps in knowledge, as well as culturally diverse ways of knowing that will shape community values and decision making. Answering the question about what is possible requires addressing both community cares and knowledge. It also requires unpacking the complexity of factors that shape conditions of possibility—factors such as existing utility structures and federal, state, and local energy policies, regulation, and incentives, but also factors such as agricultural policy and land zoning as well as land availability, roof engineering, municipal debt burdens, and the various forms of capital, including

economic as well as knowledge and temporal capital that will shape a community's ability to navigate existing regimes, or challenge and change them.

The advantages of solar energy are potentially wide-ranging, including environmental, economic, technological, distributional, and social impacts associated with justice and equity; yet, these benefits are widely dependent on how PV development takes place, including not only siting and scale considerations, but also ownership, participation, and other social factors. The limitations of PV, including the need for land access, the complexities of ownership and distribution, and the demand for energy storage for balancing production and consumption, can all arguably be addressed more effectively by using a decision-making framework that centers community values, social priorities, and participatory processes. There is an urgent need to adopt frameworks, such as the one described above, to correct the harm caused by the use of previous models in development contexts, and to build social learning and social engagement into the processes of PV development.

Solar energy technology has enormous potential. Its flexibility is an enormous asset for being able to deploy solar in ways that align with community priorities and values. By centering communities rather than technologies, the framework proposed here can encourage energy transitions that have community support because they align with community priorities. Applying this framework to solar energy technology reveals the vast potential of this technology as well as this framework, but also reveals the challenges and potential hurdles that could shape successful deployment. Addressing these challenges to rapidly promote solar energy technology development that enhances energy sovereignty and community wellbeing is essential for addressing the catastrophic consequences of the global climate crisis being caused by the use of fossil fuels, and for promoting the social justice consequences of a democratized energy system.
